## 144 **1.0 BACKGROUND**

145

146 A number of scientific and policy initiatives beginning in the mid to late 1990s have resulted in  
147 increased attention to considerations of the risk to fetuses, infants, and children and consideration  
148 of how such risks should be evaluated. The U.S. EPA is explicitly mandated to consider fetuses,  
149 infants and children as potentially sensitive subpopulations. In 1995, EPA established an  
150 agency-wide policy that calls for consistent and explicit consideration of the risk to infants and  
151 children in all risk assessments and characterizations, as well as in environmental and public  
152 health standards (Memorandum from the Office of the Administrator, October 20, 1995). The  
153 Food Quality Protection Act (FQPA) of 1996 mandated that, in setting pesticide tolerances, an  
154 additional ten-fold margin of safety be applied to infants and children to take into account  
155 potential pre- and post-natal toxicity and completeness of the data with respect to exposure and  
156 toxicity to infants and children, but noted that “the Administrator may use a different margin of  
157 safety for the pesticide chemical residue only if, on the basis of reliable data, such margin will be  
158 safe for infants and children.” The Safe Drinking Water Act amendments of 1996 also stipulated  
159 that in establishing Maximum Contaminant Levels (MCLs) the Agency shall consider “the effect  
160 of such contaminants upon subgroups that comprise a meaningful portion of the general  
161 population (such as infants, children, pregnant women, the elderly, individuals with a history of  
162 serious illness or other subpopulations) that are identifiable as being at greater risk of adverse  
163 health effects due to exposure to contaminants in drinking water than the general population.”  
164 On April 21, 1997, President Clinton signed an Executive Order (13045) that federal health and  
165 safety standards must include an evaluation of the potential risks to children in planned  
166 regulations.

167

168 Similar policies have been initiated in Europe and Canada to evaluate more fully the potential  
169 differences in risk from chemical exposure to children. For example, a recent report by the  
170 European Environment Agency (EEA) and the World Health Organization (WHO) identified  
171 policy priorities for protecting children’s health from environmental hazards (EEA and WHO  
172 2002). The European Union also recently announced a new initiative, **Science, Children,**  
173 **Awareness, EU Legislation and Continuous Evaluation (SCALE)**, focusing on children. In

174 addition, Canada's Pesticide Management Regulatory Agency has developed a policy notice  
175 regarding children (Health Canada 2002), and the National Institute of Public Health and the  
176 Environment (RIVM) in the Netherlands has conducted research on pharmacokinetics of  
177 xenobiotics in children (de Zwart et al. 2002).<sup>1</sup>

178  
179 These differences have led to research by a number of investigators comparing kinetic  
180 parameters in adults and children, and, where possible, comparing internal dose in adults and  
181 children. A number of studies have reviewed physiological and metabolic differences between  
182 adults and children (e.g., Renwick 1998; Ginsberg et al. 2002; Scheuplein et al. 2002; Wolterink  
183 et al. 2002; de Zwart et al. 2004; IPCS 2007). Determining the impact of these differences on  
184 internal dose is challenging. However, data on pharmaceuticals have been used to evaluate age-  
185 related differences in such parameters as clearance, half-life, area under the blood concentration-  
186 time curve (AUC) and blood concentration, and the resulting impact on internal dose (Renwick  
187 1998; Renwick et al. 2000; Ginsberg et al. 2002, 2004; Hattis et al. 2003). These latter studies  
188 have concluded that the major differences are in the first six months of life, primarily in the first  
189 two months.

190  
191 Hattis, Ginsberg, and colleagues have developed a substantial database of kinetic parameters for  
192 44 chemicals (primarily pharmaceuticals), available at <http://www2.clarku.edu/faculty/dhattis>.  
193 This database has been used for a number of analyses describing variability of half-life with age  
194 and by metabolic enzyme class (e.g., CYP3A substrates, CYP1A2 substrates, etc.) (Ginsberg et  
195 al. 2002, 2004). These studies found that the average ratio of child:adult half-life for all  
196 substrates, and for most individual classes, was greater than 3 for premature neonates. The  
197 average ratio was also elevated for full-term neonates through about two months, depending on  
198 the substrate. The child half-life tended to be less than adult half-life in the six-month to two-

---

<sup>1</sup> The risk to adults and children could differ due to differences in exposure, toxicodynamics, or toxicokinetics. (Unless otherwise specified, the term *child* is used in this report to refer to the entire period between birth and attainment of physical and sexual maturity.) For example, differences in intake parameters or activity patterns (e.g., hand-to-mouth behavior in infants, children playing in dirt) can affect exposure. Toxicodynamic differences may result from windows of increased susceptibility in developing tissues. In addition, damage to developing tissue may manifest at a later stage in growth (de Zwart et al. 2002). Toxicokinetic differences may result from numerous age-related differences in absorption, distribution, metabolism, and excretion, and their resulting effect on internal dose of the active form of the chemical. These differences have been catalogued in numerous papers. This report focuses on the impact of toxicokinetic differences between adults and children.

199 year age range, with lower half-lives sometimes extending through 12 years, depending on the  
200 substrate.

201  
202 These analyses, based primarily on pharmaceutical data, provide much useful information  
203 regarding the impact of age-related kinetic differences. However, there are a number of issues  
204 that need to be considered in extrapolating such data to environmental chemicals. Many of these  
205 issues have been described by Clewell et al. (2004). They include: (1) pharmaceuticals are  
206 usually water-soluble, while environmental chemicals are often lipophilic; (2) different  
207 metabolic systems may apply; (3) the parent is usually (though not always) the active agent for  
208 pharmaceuticals, while competing activation and detoxification reactions may be important for  
209 environmental chemicals; (4) pharmaceutical data are primarily for administration via the oral  
210 route; and (5) exposure to pharmaceuticals is usually at doses designed to cause an effect,  
211 meaning that it is at the upper end of the dose-response curve for therapeutic effectiveness, while  
212 exposure to environmental chemicals is typically at the low end of the dose-response curve. An  
213 additional factor is that much of the data collected on pharmaceuticals are based on half-life, and  
214 differences in half-life do not necessarily translate directly into differences in clearance (which is  
215 inversely related to AUC). Half-life needs to be corrected for volume of distribution to be  
216 related to clearance. While Ginsberg et al. (2002) concluded that differences in volume of  
217 distribution did not affect the elimination half-life for the drugs they studied, differences in  
218 volume of distribution may be more important for chemicals that are lipophilic, concentrate in  
219 other tissues, or bind significantly to plasma proteins.

220  
221 To address these considerations, a number of analyses have been conducted with a focus on  
222 environmental chemicals. Age-specific metabolic and physiological data have been collected  
223 and collated in several studies (Renwick 1998; Hattis et al. 2003). PBPK models and other  
224 kinetic analyses (Haddad et al. 1999; Pelekis et al. 2001; Sarangapani et al. 2003; Ginsberg et al.  
225 2004a; Clewell et al. 2004; Ginsberg et al. 2005; Price et al. 2003; Nong et al. 2006) and particle  
226 dosimetry models (Martonen et al. 2000; Ginsberg et al. 2005; Jarabek et al. 2005) have been  
227 used by several authors to evaluate age-related differences in kinetics. Consistent with results  
228 reported for pharmaceuticals (Renwick et al. 2000; Hattis et al. 2003), these authors found that  
229 the largest differences were in the first year of life. The largest differences were observed at the

230 earliest time point (1 month of age), and differences were generally in the range of two-fold or  
231 less by 1 year. This is consistent with the early immaturity and development of enzyme systems.

232  
233 As part of a project of the International Life Science Institute (ILSI) on evaluating children's risk  
234 from exposure to environmental chemicals, Daston et al. (2004) developed a framework for  
235 assessing children's risk, ranging from problem formulation through analysis and risk  
236 characterization, and Ginsberg et al. (2004) presented a framework for considering toxicokinetic  
237 issues related to children's risk, highlighting a number of questions and issues that need to be  
238 considered.

239  
240 The purpose of this current report is to build on the frameworks developed as part of the ILSI  
241 process. The framework presented here (Figure 1) presents an analytical approach for evaluating  
242 the relative tissue dosimetry in adults and children for inhaled gases. Case studies were  
243 conducted for systemic effects of gases under various metabolic scenarios to provide some  
244 perspective on the potential range of internal dose in children and adults for various  
245 combinations of physicochemical characteristics and mode of action. Illustrative analyses are  
246 also presented on relative dosimetry for chemicals that show significant age-related variability in  
247 enzyme capacity. To illustrate the application of the framework and demonstrate consistency  
248 with more data-intensive approaches, the results of these analyses were compared with the  
249 results obtained using PBPK modeling for chemicals with similar metabolic characteristics.

250  
251 The framework presented here reflects the input from a peer consultation with an expert panel.  
252 The initial peer consultation on an early draft provided substantial input on the structure of the  
253 framework. Based on this input, additional analyses were conducted, and a second peer  
254 consultation is being held to consider the revised framework, including the bounding analyses  
255 and case studies conducted as part of verification of the framework.

256  
257 The framework focuses on the dosimetric comparison, i.e., a comparison of the mean internal  
258 dose in adults and children. This information is useful both for analyses of individual chemicals,  
259 and to aid risk assessors in identifying the parameters and chemical characteristics that result in  
260 children receiving a higher (or lower) internal dose than adults. Such information can provide

261 useful perspective to individual chemical assessments, and can focus efforts for obtaining  
262 additional data and for more refined analyses to those cases and categories of chemicals where  
263 there is the greatest potential or likelihood of children being at greater risk. Although the focus  
264 is on mean dose, risk assessors and risk managers can use the dosimetry data, combined with  
265 information on variability, to evaluate the adequacy of default uncertainty factors for protecting  
266 children, or to determine if chemical-specific modifications to uncertainty factors are needed to  
267 adequately protect children. While there are a number of areas in which this initial framework  
268 can be enhanced and expanded, the intent is to provide a structure that highlights key issues and  
269 identifies some standard approaches. It is hoped that this report and framework will serve as a  
270 starting point for more in-depth analyses, and to focus generic and chemical-specific research on  
271 the key issues for addressing children’s risk due to kinetic differences.

272

## 273 **2.0 FRAMEWORK**

274

### 275 **2.1 Overview**

276

277 Figure 1 presents the draft framework for evaluating age-related differences in inhalation  
278 dosimetry and the resulting impact on internal dose. This framework, as well as the associated  
279 analyses presented below, is designed to help the risk assessor choose the appropriate tools and  
280 approaches to be applied for evaluating dosimetry differences between adults and children, as  
281 well as to identify chemical characteristics leading to markedly higher or lower internal dose for  
282 children compared to adults.

283

284 The first step in this process is to consider the duration of exposure, the nature of the critical  
285 effect and the mode of action for that effect. The initial decision point in this framework relates  
286 to the duration of exposure for which child-adult comparisons of dosimetry are intended.

287 Chronic exposures will generally follow the right-hand side of the framework. The exception is  
288 if there is a window of vulnerability (based on toxicodynamic considerations). Such a critical  
289 window would mean that the effects and dosimetry associated with a shorter-term exposure  
290 would drive the assessment, and therefore the exposure would be considered using the same  
291 approach as used for acute exposures. Therefore, the left-side arm of the diagram will be  
292 described as “acute” for the rest of this discussion. The next consideration, applicable to both

293 arms of the diagram, is whether the critical effect is systemic (i.e., remote effects) or local (i.e.,  
294 portal of entry effects)<sup>2</sup> in nature. For gases and vapors that cause local effects (e.g., highly  
295 reactive or water soluble gases), the child-adult comparison is based on dose to the specific  
296 regions of the respiratory tract (section 2.2). However, for systemically-acting gases and vapors,  
297 child-adult comparisons would be based on active form (parent chemical or metabolite), its level  
298 (concentration or amount), and intensity (peak, average or integral), calculated using  
299 pharmacokinetic models and equations that reflect the attainment or not of steady-state during  
300 the specified exposure condition (section 2.3).

301

## 302 **2.2 Evaluating child-adult differences in dosimetry of gases and vapors causing portal** 303 **of entry effects (Category 1 and 2 gases under the U.S. EPA RfC scheme):** 304

305 For chemicals that are highly reactive or highly water soluble, effects are often local in nature  
306 and as such estimates of the delivery of chemical to the various regions of the respiratory tract  
307 should be obtained. Typically the Category 1 gases and vapors do not accumulate significantly  
308 in blood, and as such systemic distribution and the extent of extrapulmonary effects is minimal  
309 or negligible (e.g., formaldehyde, hydrogen fluoride, chlorine, volatile organic esters). Category  
310 2 gases (e.g., ozone, sulfur dioxide, xylenes, propanol) are moderately water soluble and rapidly  
311 reversibly reactive or slowly irreversibly metabolized in the respiratory tract. This lower  
312 reactivity means that they can both cause respiratory tract effects and accumulate in the blood,  
313 causing systemic effects.

314

315 For the respiratory tract effects of Category 1 and 2 gases, the airway regions such as larynx,  
316 trachea, bronchi and bronchioles cannot be considered as inert tubes carrying the chemical to the  
317 alveolar region. For these chemicals, several modeling approaches are useful, including the  
318 more sophisticated CFD (computational fluid dynamics) descriptions, that take into account the  
319 regional mass transfer coefficients, as well as surface area and ventilation rates (US EPA 1994;  
320 Kimbell et al. 1993; Asgharian et al. 1995; Hanna et al. 2001; Bogdanffy and Sarangapani 2003).  
321 Data on ventilation rates and pulmonary surface area for children of various age groups as well

---

<sup>2</sup>Respiratory effects occasionally occur as the result of systemic exposure from the endothelial side of the cell layer, or as a combination of both direct contact effect and systemic exposure. Such effects would be addressed using both the methods for systemic and portal of entry dosimetry.

322 as adults are available in the literature (Clewell et al. 2002; Snodgrass 1992; Plunkett et al. 1992;  
323 U.S. EPA 1997). Hofmann (1982) published empirical equations to determine the length and  
324 diameter of the trachea, bronchial airways, and alveoli diameter in children as a function of age.  
325 These data, integrated within full-blown regional dosimetry models or steady-state solutions for  
326 these models, as appropriate, can be used to compute the child-adult differences in regional  
327 dosimetry (Hoffman 1982; Overton and Graham 1989; Martonen et al. 1989). In these  
328 approaches, the mass transported per surface area per unit time is calculated as follows:

$$\text{Flux} = V_E/SA (C_i - C_x) \quad \text{Equation 1}$$

330 where  $V_E$  is the ventilation rate, SA is the surface area of the region of interest, and  $C_i$   
331 and  $C_x$  are the inlet and outlet concentrations, respectively (Hanna et al. 2001).

332  
333  
334 Depending upon the mode of action, the flux or another measure of dose metric (e.g., peak tissue  
335 concentration ( $C_{max}$ ), area under the tissue concentration vs time curve (AUC)) may be  
336 computed for evaluating child-adult differences in regional dosimetry gases and vapors causing  
337 direct respiratory tract effects. If the parent chemical is the toxic moiety implicated in the portal  
338 of entry effects, then the appropriate dose metric is likely to be  $C_{max}$  for acute effects and AUC  
339 for chronic effects. When additional data on the nature and extent of toxic moiety-tissue  
340 interaction exist, they may permit the use of other mechanistically relevant dose metrics (e.g., pH  
341 alteration resulting from exposure to vinyl acetate, [Bogdanffy et al. 2001]).

### 342 343 **2.3 Evaluating child-adult differences in dosimetry of gases and vapors causing** 344 **systemic effects (Category 2 and 3 gases under the U.S. EPA RfC scheme):** 345

346 Category 3 gases are relatively water-insoluble, with little reactivity in the respiratory tract and  
347 perfusion-limited uptake in the pulmonary region, uptake in the blood, and toxic effects usually  
348 occurring remotely. The approaches described in this section also apply to systemic effects of  
349 Category 2 gases. However, because Category 2 gases also react in the respiratory tract, the  
350 steady state equations described in this section may be less accurate for those gases. Differences  
351 between respiratory tract dose in adults and children (and therefore differences in the amount of  
352 chemical available for uptake to the blood) are not fully captured by the steady state equations

353 presented here, but both the general approach of the framework and the general trends illustrated  
354 in the case studies in Section 3.3 would also apply to Category 2 gases.

355  
356 For systemically-acting gases and vapors, the inhalation dosimetric adjustment between animals  
357 and humans has been conducted on the basis of the ratio of blood:air partition coefficients (U.S.  
358 EPA 1994). This approach, applied in the absence of PBPK models, is most appropriate when  
359 (i) the parent chemical is the toxic moiety, (ii) hepatic and extrahepatic metabolism processes are  
360 not significant, and (iii) the arterial blood concentration attains steady-state during the relevant  
361 duration of exposures. Accordingly, for evaluating the child-adult differences in the dosimetry of  
362 Category 3 chemicals, the differences in blood:air partition coefficients may be evaluated.

363 However, due to existing evidence on the child-adult differences in metabolic clearance, the  
364 direct application of the RfC default approach to evaluate age-related dosimetry differences for  
365 Category 3 gases and vapors may not be adequate. As indicated in Figure 1, the evaluation of  
366 child-adult differences in dosimetry for these chemicals may be conducted on the basis of  
367 whether the endpoint of interest is caused by the parent or a metabolite. For many chronic toxic  
368 effects, the concentration of the toxic form of chemical in target tissue integrated over time has  
369 been considered to be a reasonable dose metric (U.S. EPA 2006). Accordingly, the child-adult  
370 comparisons of internal dose of Category 3 chemicals may be conducted using the AUC or daily  
371 average of the dose metric. When the parent chemical is the toxic form, the average  
372 concentration in arterial blood (proportional to the AUC) during chronic exposures can be  
373 computed as: dose rate/clearance. Whereas the dose rate is determined by the inhaled  
374 concentration and alveolar ventilation rate, the clearance is the net result of the pulmonary,  
375 metabolic (hepatic and extrahepatic) as well as renal elimination processes, all of which are to  
376 known vary as a function of age (Clewell et al. 2002).

377  
378 The next consideration is whether the toxic effect is due to the parent, a stable metabolite, or a  
379 reactive metabolite. IPCS (2005) discusses considerations and data that can be used to make this  
380 determination.

381

382 The child-adult differences in dosimetry of Category 3 gases and vapors, for which parent  
383 chemical is the toxic moiety, can be evaluated using a steady-state algorithm of the following  
384 form:

$$385 \quad CA_{ss} = \frac{QP * CI}{QP/PB + QL * E} \quad \text{Equation 2}$$

388 where  $CA_{ss}$  is the arterial blood concentration;  $QP$  is the alveolar ventilation rate,  $CI$  is  
389 the chemical concentration in inhaled air,  $QL$  is liver blood flow,  $E$  is hepatic extraction ratio;  
390 and  $PB$  is the blood:air partition coefficient.

391  
392 Using the age-specific values for each of the above parameters,  $CA_{ss}$  can be computed and  
393 compared among the different age groups. There is no need to perform calculations of steady-  
394 state concentrations of chemicals in target tissues (as opposed to arterial blood concentration)  
395 because: (i) target tissue concentrations are proportional to  $CA_{ss}$  as defined by the partition  
396 coefficients (Lam et al. 1982; Krishnan 2007; Pelekis et al. 1997), and (ii) there is no evidence to  
397 date that indicates the tissue water and lipid contents would be significantly different,  
398 particularly for children aged >3 months in comparison with adults (Price et al. 2003; White et  
399 al. 1991; Woodward and White 1986).

400  
401 For Category 3 gases which exert their toxicity via the formation of reactive metabolites, the  
402 child-adult dosimetry comparison can be conducted on the basis of the rate of metabolism in the  
403 tissue (i.e., amount per L tissue per unit time). The steady-state rate of metabolism (i.e., average  
404 during chronic exposures) may be calculated on the basis of the steady-state arterial blood  
405 concentration (Equation 3). In this case then,

$$406 \quad AMT = (CA_{ss} * QL * E) / VL \quad \text{Equation 3}$$

408 where  $AMT$  = amount of metabolite formed per unit time per unit volume of tissue,  $CA_{ss}$   
409 = arterial blood concentration of the parent chemical,  $QL$  = hepatic blood flow rate,  $E$  = hepatic  
410 extraction ratio and  $VL$  = liver volume.

411

412 For Category 3 chemicals producing stable or circulating metabolites, the rate of clearance of the  
413 metabolite in both adults and children should be additionally taken into account for calculating  
414 the dosimetry differences (Figure 1). In the case of metabolites, the clearance via kidney is  
415 likely to become more important (compared to parent form of Category 3 gases) such that child-  
416 adult differences in glomerular filtration rate (Clewell et al. 2002) might play an important role  
417 in determining the magnitude of the dose differences between various age groups. The steady-  
418 state equation in such cases would be of the following form:

$$419 \quad C_{met} = \frac{CA_{ss} \times QL \times E}{CL_{metabolite}} \quad \text{Equation 4}$$

422 Steady-state is achieved rapidly for gases and vapors that have a low volume of  
423 distribution and those that are cleared effectively by the biochemical processes. Category 3  
424 gases generally have low blood:air partition coefficients but variable fat:blood partition  
425 coefficients (Table 1). U.S. EPA (1994), based on PBPK modeling in rats, indicated that  
426 steady-state is attained during subchronic or chronic inhalation exposures to gases with a  
427 blood:air partition coefficient < 100 and fat:blood partition coefficient < 100. In effect, almost  
428 all of the known Category 3 gases and vapors are expected to attain steady-state during  
429 continuous inhalation exposures in humans, even though only the proof of concept is available  
430 (Pelekis et al. 1997). In such cases, the use of a steady-state algorithm is likely to be sufficient  
431 for evaluating child-adult differences in dosimetry. The same approach is applicable to “acute”  
432 scenario, if the parent compound is the toxic agent and steady state is reached. However if the  
433 steady state is not reached in the “acute” scenario, regardless of whether toxic moiety is the  
434 parent chemical or metabolite (reactive or stable), the child-adult difference in systemic uptake  
435 and internal dose may be computed using full-blown physiologically-based pharmacokinetic  
436 (PBPK) models.

437  
438 It is recognized that for several chemicals, based on the current state of knowledge of the mode  
439 of action, greater or less information may be available. For example, information on the extent  
440 of receptor occupancy, DNA adducts in target site, depletion of glutathione in target tissues, etc.  
441 can be used for estimating the child-adult differences in internal dose; however, such data are  
442 often not available. In fact, for many chemicals, the appropriate dose metric is not known. In

443 such cases, it is reasonable to use the AUC of the parent chemical as the dose surrogate (U.S.  
444 EPA 2000, 2006; Clewell et al. 2002) and evaluate the child-adult differences in dosimetry. This  
445 is consistent with the approach for calculating Human Equivalent Concentrations (HECs) under  
446 the U.S. EPA's RfC guidance (U.S. EPA 1994). However, in such cases, the assessor should  
447 note the uncertainty introduced by this assumption, and include appropriate caveats.

448  
449 For some chemicals, limited information may be available for the estimation of chemical-  
450 specific kinetic parameters needed for the application of the proposed framework. In those  
451 cases, information from a surrogate compound with similar chemical properties or structure  
452 activity relationships may be useful in evaluating potential child-adult differences. For example,  
453 Beliveau et al. (2003, 2005) used quantitative structure-property relationships to estimate  
454 partition coefficients and hepatic clearance for a number of volatile organic compounds. Again,  
455 the risk assessors would need to consider any uncertainty introduced by the reliance upon  
456 information for a surrogate.

457

### 458 **3.0 ANALYSES: APPLICATION OF THE CHILD-ADULT** 459 **FRAMEWORK TO CHEMICALS WITH SYSTEMIC EFFECTS** 460 **(CATEGORY 2 AND CATEGORY 3 GASES)**

461

#### 462 **3.1 Introduction**

463

464 The magnitude of child-adult differences in internal dose of Category 3 gases and vapors has  
465 been evaluated using age-specific physiological data as well as chemical-specific partitioning  
466 and clearance data in PBPK models or steady-state algorithms (Price et al. 2003; Pelekis et al.  
467 2003; Clewell et al. 2004; Ginsberg et al. 2002; Hattis et al. 2003; Sarangapani et al. 2003). As  
468 outlined in Section 2, steady-state algorithms are adequate for estimating the magnitude of child-  
469 adult difference in the dosimetry of Category 3 gases when the toxic moiety is the parent  
470 chemical or a metabolite. The steady-state approach requires the knowledge of certain  
471 parameters that are known to vary as a function of age: alveolar ventilation rate, hepatic blood  
472 flow, liver volume and clearance (renal, hepatic and/or pulmonary). Most of the previous  
473 analyses estimated the child-adult magnitude in internal dose of Category 3 gases and vapors,  
474 using physiological parameters for children (particularly neonates) derived from adult values on

475 the basis of an allometric or regression relationships (Clewell et al. 2004; Ginsberg et al. 2002;  
476 Sarangapani et al. 2003). In order to facilitate a broader understanding of the extent of child-  
477 adult differences in dosimetry for Category 3 gases as well as to identify situations and  
478 parameters leading to maximal magnitude of child-adult differences in the dosimetry for these  
479 gases, the present study conducted a number of bounding analyses and case studies in various  
480 age groups: (neonates (3 months), toddlers (1 year), preschooler (5 years), middle schooler (10  
481 years)). Accordingly, calculations of internal dose (i.e., steady-state concentration of parent  
482 chemical in blood, steady-state concentration of reactive metabolite in liver, and steady-state  
483 concentration of circulating metabolite in the body) in adults and children of various age groups  
484 were performed by setting hepatic clearance in children equal to (1) zero, (2) blood flow rate to  
485 the organ, or (3) a fraction of metabolic capacity of adults based on information on delayed  
486 enzyme ontogeny.

487

## 488 **3.2 Approach**

489

### 490 **3.2.1 Child-adult differences in dosimetry for Category 3 gases for which parent chemical** 491 **is the toxic moiety**

492

493 The steady-state blood concentration of Category 3 gases that are metabolized primarily in liver  
494 and eliminated by clearance processes in both liver and lung can be calculated with the  
495 knowledge of age-specific blood:air partition coefficient ( $P_b$ ), alveolar ventilation rate ( $Q_P$ ),  
496 hepatic blood flow rate ( $Q_L$ ) and intrinsic clearance ( $CL_{int}$ ) (Andersen 1981; Pelekis et al. 1997;  
497 Csanady and Filser 2001; Clewell et al. 2004). Available information suggest that neither the  
498 blood:air partition coefficient nor the composition of blood (lipid and water content) vary  
499 markedly as a function of age (Table 2) (Berenson et al. 1982; Lerman et al. 1984; White et al.  
500 1991; Family Practice Notebook 2005). Therefore, the evaluation of child-adult differences in  
501 parent chemical concentrations can be performed with the knowledge of  $Q_P$ ,  $Q_L$  and  $CL_{int}$  for  
502 the various age groups, as well as using the  $P_b$  value for one of the age groups (usually adults).

503

504 The computation of steady-state blood concentration of Category 3 gases was performed on the  
505 basis of Eqn. 2 of the framework:

506

507  $CA_{ss} = \frac{QP * CI}{CLp + CLh}$   
 508  
 509 where  $CA_{ss}$  = steady-state arterial blood concentration ( $\mu\text{g/L}$ ),  $QP$  = alveolar ventilation  
 510 rate (L/h),  $CI$  = inhaled concentration ( $\mu\text{g/L}$ ),  $CLp$  = pulmonary clearance (=  $QP$  divided by  
 511 blood:air partition coefficient ( $PB$ )) and  $CLh$  = hepatic clearance (=  $CL_{int} \times QL / (CL_{int} + QL)$ )  
 512 where  $CL_{int}$  = intrinsic clearance (= maximal velocity divided by Michaelis constant) and  $QL$  =  
 513 hepatic blood flow rate (L/h).

514  
 515 The upper-bound of the magnitude of child-adult difference in  $CA_{ss}$  was calculated, initially, by  
 516 assuming minimal metabolism in children (i.e.,  $CLh = 0$ ) and maximal metabolism in adults (i.e.,  
 517  $CLh$  = hepatic blood flow rate) such that the hepatic extraction ratio equals 1. The calculations  
 518 conducted under this scenario focused on identifying the maximal child-adult factor that is likely  
 519 to be associated with Category 3 gases and vapors for which the parent form represents the toxic  
 520 moiety. A second bounding analysis was conducted using Eqn. 2 for highly metabolized  
 521 chemicals, for which hepatic clearance is blood-flow limited in both adults and children. The  
 522 resulting child-adult ratios of  $CA_{ss}$  from this scenario would essentially reflect the lower-bound  
 523 of the child-adult differences in internal dose. A third scenario involved the use of age-specific  
 524 data on metabolizing enzyme capacity in Eqn. 2. Enzyme ontogeny data were used to estimate  
 525  $CL_{int}$  in children on the basis of adult values as follows (Clewell et al. 2004; Nong et al. 2006):

526  
 527  $CL_{intChild} = CL_{intAdult} * F * VL_{Child} / VL_{Adult}$ ,  
 528 where  $VL$  is the volume of liver and  $F$  is the enzyme activity as a fraction of the adult  
 529 value. This particular approach was applied to hepatic CYP2E1 and alcohol dehydrogenase  
 530 (ADH) using data summarized by Clewell et al. (2004).

531  
 532 **3.2.2 Child-adult differences in dosimetry for Category 3 gases for which reactive**  
 533 **metabolite is the toxic moiety**  
 534

535 For Category 3 gases exerting toxicity via reactive metabolites, the child-adult dosimetry  
 536 comparisons of internal dose (i.e., amount per L tissue per unit time) was computed on the basis  
 537 of Eqn. 3 of the framework:

538

539  $AMT_{\text{Reactive metabolite}} = (CA_{ss} \times CL_h)/VL$

540 The magnitude of child-adult differences in internal dose was calculated for the three  
541 scenarios described in section 3.1. Accordingly, the  $CL_h$  value was first set to 0 in children and  
542 to  $QL$  in adults, as a bounding case. Then, the  $CL_h$  was set equal to hepatic blood flow in both  
543 children and adults, to compute an upper bound of the child-adult difference in internal dose of  
544 reactive metabolites. Finally, the age-specific  $CL_h$  was computed according to the information  
545 on the relative content of metabolizing enzyme (CYP2E1, ADH) in children relative to adults.

546

547 **3.2.3 Child-adult differences in dosimetry for Category 3 gases for which circulating**  
548 **metabolite is the toxic moiety**

549

550 As noted above, for calculating the internal dose of stable or circulating metabolites, the  
551 clearance of metabolites subsequent to their formation should be taken into account (Krishnan  
552 and Andersen 1991; Sarangapani et al. 2003; Gentry et al. 2002). Because kidney clearance is  
553 likely to play an important role for such metabolites, child-adult differences in glomerular  
554 filtration rate need to be taken into account in determining the magnitude of the dose differences  
555 between various age groups. The steady-state equation for computing the internal concentration<sup>3</sup>  
556 of circulating metabolites (as shown in section 2.3) is:

557

558  $C_{\text{Stable metabolite}} = \frac{CA_{ss} \times QL \times E}{CL_{\text{metabolite}}}$

559

560 The magnitude of child-adult differences in internal dose was initially calculated for the  
561 three scenarios described in section 3.2.1. (i.e., bounding case, flow-limited clearance, delayed  
562 ontogeny of metabolizing enzymes). For all three scenarios,  $CL_{\text{metabolite}}$  was assumed to be  
563 adequately represented by renal clearance which was set equal to the age-specific value of  
564 glomerular filtration rate (GFR). Additionally, calculation of  $C_{\text{Stable metabolite}}$  was done for a  
565 situation in which  $CL_{\text{metabolite}}$  is determined by both renal and metabolic clearance processes,  
566 subsequent to flow-limited metabolism of parent chemical in adults and children. This particular  
567 scenario facilitates the evaluation of an extreme case of child-adult difference in internal dose, in  
568 which the capacity-limited difference in clearance of metabolite and flow-limited clearance of

---

<sup>3</sup> Because the dose metric of interest is the concentration of the chemical, comparison of concentrations can be considered a comparison of internal dose.

569 parent chemicals might both apply and result in higher child-adult dose ratio (Clewell et al. 2004;  
570 Sarangapani et al. 2003; Ginsberg et al. 2005).

571

### 572 **3.2.4 Parameter and data sources**

573

574 For the analyses presented here, the value of CI for all age groups was set to 1  $\mu\text{g/L}$  in air. The  
575 physiological parameters (QP, QL and VL) for the children of various age groups were obtained  
576 from Price et al. (2003), whereas those for adults were obtained from Arms and Travis (1988).

577 The delayed development of renal function (GFR) and liver metabolism (CYP2E1, ADH) in  
578 children was expressed as a fraction of the adult value based on data summarized by Clewell et  
579 al. (2004) and Sarangapani et al. (2003). For the various calculations, CL<sub>int</sub> was varied from 0.1  
580 L/hr (capacity-limited metabolism) to 1000 L/hr (flow-limited metabolism), and the PB was  
581 varied between 0.1 and 50 (which generally reflects the values for commonly known Category 3  
582 gases and vapors (Table 1)). The internal dose at steady-state was calculated using Microsoft  
583 EXCEL® for each age group using Eqns. 2 – 4, and then the child-adult factors were derived for  
584 each of the three scenarios as ratios of internal doses.

585

## 586 **3.3 Results**

587

### 588 **3.3.1 Child-adult differences in dosimetry for Category 3 gases for which parent chemical** 589 **is the toxic moiety**

590

591 Figures 2-3 summarize the results of child/adult steady-state concentration ratios for the first two  
592 scenarios of bounding cases, (1) upper bound based on zero metabolism in children of all age  
593 groups and maximal metabolism (i.e., equal to hepatic blood flow) in adults (scenario 1), and (2)  
594 lower bound based on flow-limited clearance in both adults and children (scenario 2). Figure 2  
595 shows that the child:adult ratio of C<sub>Ass</sub> would increase with increasing PB for scenario 1 when  
596  $E_{\text{child}} = 0$  and  $E_{\text{adult}} = 1$ . For this worst-case scenario, hepatic clearance was set to zero for all  
597 four ages of children, and so only one curve is shown. The increase of the child:adult ratio of  
598 C<sub>Ass</sub> is a direct result of the fact the C<sub>Ass</sub> in children in this scenario is determined only by  
599 pulmonary clearance, whereas in adults it is determined additionally by CL<sub>h</sub>. For chemicals with  
600 very low CL<sub>int</sub> values (e.g., 0.01 L/hr), hepatic clearance (CL<sub>h</sub>) is negligible compared to

601 pulmonary clearance ( $CL_p$ ) such that the child/adult ratio of  $C_{Ass}$  approximates the ratio of  $PB$   
602 in child and adult, which essentially is 1. For increasing  $CL_{int}$  values, however, the child/adult  
603 ratio exceeds 1, with the actual magnitude being determined by the relative contributions of  
604 pulmonary clearance and hepatic clearance to total clearance in adults as well as the extent of the  
605 deviation of total clearance in adults from the pulmonary clearance in children. If  $CL_{h_{adults}}$  is  
606 near full capacity and  $CL_{h_{child}}$  is near zero (worst case scenario), then the child/adult ratio of  
607  $C_{Ass}$  will continue to increase as a function of  $PB$  (Figure 2). At any given  $PB$  value, the lower  
608 bound of child/adult ratio for parent chemical dose can be simulated by assuming blood flow-  
609 limited metabolism in both adults and children (scenario 2; Figure 3). In this case, the maximal  
610 value of child/adult ratio of  $C_{Ass}$  (2.1) is associated with the age group of 3 month-old and gases  
611 with high  $PB$  values (e.g., 50) (Figure 3). When age group-specific metabolic capacity is known,  
612 a better estimate of the magnitude of child/adult ratio of  $C_{Ass}$  can be obtained, which should be  
613 between the upper and lower bound estimates presented above, as shown in scenario 3 with ADH  
614 and CYP2E1 as examples.

615  
616 The results of the steady-state analysis for  $C_{Ass}$  based on age-dependent CYP2E1 and ADH  
617 activity are shown in Figures 4a and 4b, respectively (scenario 3)<sup>4</sup>. In both cases, the 3 month  
618 old, the youngest group evaluated, has the greatest difference in parent concentration relative to  
619 the adults. This is not surprising since the ADH and CYP2E1 are at the lowest levels at birth,  
620 and gradually increase to adult levels. Similar to the results obtained for scenarios 1 and 2, the  
621 highest child/adult ratio for  $C_{Ass}$  (approximately 2.3 for ADH) (Figure 4b) was associated with  
622 high  $CL_{int}$  values (i.e., 1000 L/hr) reflective of flow-limited metabolism in adults but not  
623 necessarily in all other age groups. For gases with very low  $CL_{int}$  values, however, the  
624 metabolism rate is unlikely to be a sensitive parameter in estimating  $C_{Ass}$  and thus the  
625 child/adult ratio is close to unity (not shown).

626

---

<sup>4</sup> Note: Ratio 3/A = 3 months:adult; 1/A = 1 year:adult; 5/A = 5 years:adult; 10/A = 10 years:adult

627 **3.3.2 Child-adult differences in dosimetry for Category 3 gases for which reactive**  
628 **metabolite is the toxic moiety**  
629

630 Figure 5 depicts the child-to-adult ratio of the internal dose of reactive metabolite resulting from  
631 continuous exposure to Category 3 gases with PB values up to 50. Here, the upper bound of the  
632 child/adult ratios (shown in Figure 5) results when metabolism is flow-limited in both adults and  
633 children whereas the lower bound (i.e., zero) is associated with scenario 1 (i.e., when  $CL_{h_{child}}$  is  
634 zero and  $CL_{h_{adults}}$  is near full capacity). The highest value of the upper-bound of child-to-adult  
635 ratios of internal dose of reactive metabolites (1.45) was obtained for 10-year-old children.  
636 Under flow-limited conditions, the internal dose of reactive metabolites is determined by  $QL/VL$   
637 which is about 33 in younger age groups (3 months to 5 years) and 47 in 10-year-old children,  
638 compared to 53 in adults (Price et al. 2003). The relative difference in these determinants  
639 between children and adults, coupled with the difference in  $CA_{ss}$  (section 3.3.1) would explain  
640 the magnitude of child-adult ratios in the liver concentration of reactive metabolites computed in  
641 this study (Figure 5).

642  
643 Using information on delayed ontogeny of metabolizing enzymes (ADH and CYP2E1), it would  
644 appear that the internal dose of reactive metabolites for poorly metabolized Category 3 gases  
645 (assuming an intrinsic clearance of 0.1 L/hour) would be lower in children of all age groups  
646 compared to adults (Figures 6 for ADH and Figure 7 for CYP2E1). In case of highly  
647 metabolized gases (e.g.,  $CL_{int} = 1000$  L/hour), however, the formation of reactive metabolites in  
648 older children (5 year old and 10 year old) and in the 3-month-old (but not in the 1-year-old)  
649 might slightly exceed the levels formed in adults (Figure 8). The quantitative behavior depicted  
650 in Figure 8 applies to both ADH and CYP2E1 (not shown).

651  
652 **3.3.3 Child-adult differences in dosimetry for Category 3 gases for which circulating**  
653 **metabolite is the toxic moiety**  
654

655 The child/adult ratios of the steady-state concentration of stable (circulating) metabolite were  
656 initially calculated on the basis of the rate of formation (i.e., hepatic metabolism of parent  
657 chemical) and rate of elimination (i.e., renal clearance of metabolite) for the three scenarios  
658 described in section 3.1. In this case, the upper bound of the child-adult ratios resulting from

659 flow-limited metabolism in both adults and children combined with renal excretion as described  
660 by the developmental data, range between 0.9 – 1.3 (Figure 9). The lower bound of the  
661 child/adult ratio of the stable metabolite is essentially zero, which is associated with scenario 1  
662 described in section 3.1. (i.e., when  $CL_{h_{child}}$  is zero and  $CL_{h_{adults}}$  is near full capacity).  
663 Calculations based on the delayed ontogeny of ADH and CYP2E1 enzymes involved in the  
664 formation of stable metabolites yield child/adult factors that are essentially in this range both for  
665 highly metabolized vapors and gases (Figures 10a for ADH and 10b for CYP2E1) and poorly  
666 metabolized ones (Figures 11a for ADH and 11b for CYP2E1).

667  
668 The rate of formation of stable metabolite is determined by QL, E and CAss. Therefore, for  
669 flow-limited metabolism in both children and adults (i.e., when  $E=1$ ), the values of QL and CAss  
670 would determine the magnitude of child/adult ratio of the amount of stable metabolites formed at  
671 steady-state. Given that child/adult ratio of CAss for Category 3 gases is within a factor of 2,  
672 and that the QL is about 14 times lower in neonates compared to adults, the overall amount  
673 formed would be several times (up to 7-fold) lower in young children. However, since the GFR  
674 is also lower in neonates compared to adults (by a factor of about 7), the net effect is that the  
675 resulting child/adult ratio of steady-state concentration of circulating metabolite is about 1. The  
676 relative dose in children could be substantially higher if there is significant child-adult difference  
677 in metabolic clearance (e.g., when  $CL_{h_{child}}$  is zero and  $CL_{h_{adults}}$  is near maximum capacity).  
678 Figures 12-13 depict the adult/child factors for highly metabolized (Figure 12) and poorly  
679 metabolized (Figure 13) Category 3 gases and vapors, for which the toxic moiety is a stable  
680 metabolite cleared efficiently in adults (i.e., flow limited process) but not at all in children (i.e.,  
681 hepatic extraction ratio = 0). The upper bound value for this child-adult difference would be  
682 approximately 17 (Figure 12); however, if the  $CL_h$  of metabolites in children varies as a function  
683 of metabolic capacity of the enzymes involved (e.g., ADH or CYP2E1), then the child/adult  
684 factors are likely to be lower than these upper bound values.

685

## 686 **4.0 DISCUSSION**

687

688 This document presents a framework for evaluating relative dosimetry in children and adults for  
689 inhaled gases. For effects at the portal of entry, a range of potential approaches are noted;

690 however, the focus of this analysis was for those gases or vapors expected to have an impact  
691 systemically, with the appropriate choice of approach depending on the chemical's mode of  
692 action. The framework presents specific considerations for systemic effects, with certain modes  
693 of action and exposure scenarios leading to recommended analytical approaches. Case studies  
694 were conducted to demonstrate the potential quantitative differences between children and adults  
695 for chemicals for which the parent, reactive metabolite, or stable metabolite is the toxic moiety  
696 of concern.

697  
698 The differences in internal dose to adults and children evaluated by the framework have the  
699 largest impact under two scenarios. The first is when there is a window of increased  
700 susceptibility. If the window of susceptibility falls during childhood, the internal dose during  
701 that period of time is a key determinant of response, and it is important to consider the relative  
702 internal dose to children and adults for a given air concentration, regardless of the total exposure  
703 duration. The second situation when differences in the child and adult dose would be of  
704 particular interest is when the exposure duration is generally comparable to or shorter than the  
705 duration of the age range of interest. Although the approach used in the framework can be used  
706 to evaluate the relative dose to children and adults in scenarios involving longer durations of  
707 exposure, the impact on response would be much smaller when the response is related to lifetime  
708 exposure (e.g., when the appropriate metric is Lifetime Average Daily Dose, or LADD). This is  
709 because estimates of cumulative dose over a lifetime resulting from exposure to low  
710 concentrations of environmental chemicals are fairly insensitive to age-related kinetic  
711 differences, because the greatest differences persist for only a short time (Pelekis et al. 1997;  
712 Clewell et al. 2004). Thus, if toxicity for the relevant endpoint is related to cumulative dose,  
713 these increases in internal dose would not have a significant effect on risk, unless a window of  
714 susceptibility coincided with the period of increased dose.

715  
716 It should also be noted that analyses presented here are a simplified approach and are not  
717 intended to be used quantitatively in risk assessment, in the absence of chemical-specific data.  
718 Instead, the intent is to identify situations in which dose metrics in the child may be substantially  
719 different from those in the adult. The proposed framework would provide a potential screen to

720 determine if the default toxicokinetic component is adequate when considering exposure to  
721 children, noting the additional need to consider variability.

722

#### 723 **4.1 Comparison with results in the literature**

724

725 The analyses presented along with the framework were conducted to provide some initial  
726 direction regarding conditions under which there are significant dosimetric differences between  
727 adults and children. The results of these analyses are consistent with individual chemical-  
728 specific analyses in the literature. They suggest that the child/adult difference in steady state  
729 arterial concentration (C<sub>ass</sub>) of the parent chemical is likely to be within a factor of 2.1 for  
730 highly metabolized Category 3 gases and vapors. This observation is consistent with the  
731 conclusions of the detailed inhalation PBPK modeling studies conducted with selected Category  
732 3 chemicals (furan: 1.5 (Price et al. 2003); styrene 1.8 and vinyl chloride 1.13 (Sarangapani et al.  
733 2003). This is also consistent with the results of Ginsberg et al. (2005), who reported that the  
734 maximal child/adult factor for steady-state arterial blood concentration of parent chemicals  
735 belonging to Category 3 was 1.75, particularly for flow-limited metabolism in both adults and  
736 neonates. In the case of poorly metabolized gases and vapors, the child/adult ratio is likely to be  
737 about 1, since child-adult differences in metabolic clearance barely have an influence on the  
738 kinetics and internal dose, as shown in this study. This observation is consistent with that of  
739 Sarangapani et al. (2003) for perchlorethylene (child/adult ratio = 1.02), a poorly metabolized  
740 Category 3 vapor. Larger child/adult ratios would result in the hypothetical case where there is  
741 no hepatic clearance in the child and high hepatic clearance in the adult, but such extreme cases  
742 were not located in the chemical literature.

743

744 Regarding Category 3 gases forming reactive metabolites, the analyses conducted here indicate  
745 that the child-adult difference would be maximal when metabolism is flow-limited in adults and  
746 children. The maximal value of child-to-adult ratios of internal dose of reactive metabolites  
747 found in the present study (1.45) is comparable to those reported for vinyl chloride (1.34) and  
748 styrene (1.83) by Sarangapani et al. (2003). The small difference between the present study and  
749 the previous studies might be due to the derivation of liver blood flow values by the previous  
750 studies on the basis of difference in liver volume between children and adults. The present

751 study, however, used liver blood flow values determined in children following radioactive gold  
752 administration (Szantay et al. 1974). The child/adult ratio of the internal dose of reactive  
753 metabolite approaches zero as the intrinsic clearance ( $Cl_{int}$ ) becomes smaller (Figures 6 and 7).  
754 This is also in agreement with the results of the PBPK modeling study by Sarangapani et al.  
755 (2003) in which the child/adult ratio for a poorly metabolized Category 3 chemical  
756 (perchloroethylene) was reported to be 0.27.

757  
758 For Category 3 gases forming stable metabolites, the analyses were based on the assumption that  
759 renal clearance would be the sole mechanism of elimination, or it considered both the renal and  
760 hepatic routes of clearance to be relevant. In the first case, the calculated ratios ranged from 0.9  
761 to 1.3. However, the child/adult ratio increased if there was a significant child-adult difference  
762 in metabolic clearance of the metabolite. In the case of Category 3 gases and vapors for which  
763 the stable metabolite (toxic moiety) is cleared efficiently in adults (i.e., flow limited process) but  
764 not at all in children (i.e., hepatic extraction ratio = 0), the child/adult ratio can be as high as 18.  
765 This is in accord with the observations of a PBPK modeling study of the formation and clearance  
766 of a stable metabolite (acetone from isopropanol), which reported a neonate/adult factor ranging  
767 from approximately 7 to 9 (Sarangapani et al. 2003). Note also that isopropanol is a Category 2  
768 gas, illustrating that the simplified steady state approaches described here give reasonable  
769 estimates of the relative systemic dose for children and adults, even for a moderately water  
770 soluble chemical. Further studies are required to systematically evaluate the relative contribution  
771 of renal, hepatic and pulmonary clearance processes to the total clearance of circulating  
772 metabolites formed from similar gases, as well as their overall contribution to the relative dose in  
773 children and adults, so as to be able to pinpoint characteristics of gases and vapors that might  
774 lead to situations where the dose to children is much higher than that to adults.

775  
776 Quantitative differences between the examples presented here and previous published analyses  
777 were generally due to differences in the age-specific parameters. For example, in addition to the  
778 differences noted above regarding age-specific liver blood flow, there were differences in the  
779 alveolar ventilation rate ( $Q_P$ ). Sarangapani et al. (2003) and Clewell et al. (2004) estimated the  
780 age-dependent alveolar ventilation as 66% of the pulmonary ventilation data compiled by U.S.  
781 EPA (1997). Because the alveolar dead space may vary with age, the current analysis focused on

782 actual measured values when possible, using the approach of Price et al. (2003). Specifically,  
783 the QP for the 3-month old used measured data from Lees et al. (1967), and Price et al. (2003)  
784 developed a regression equation to calculate the QP values for ages 1, 5 and 10 years. Inputs to  
785 the development of the regression equation were age-specific data on respiratory frequency and  
786 tidal volume, and an equation relating physiological dead space to body weight

787  
788 The results presented here are also consistent with those of Ginsberg et al. (2005), who identified  
789 several conditions under which greater metabolite levels may occur in the infant liver than the  
790 adult liver. These conditions include: (1) highly metabolized gases; (2) Category 3 gases at 1  
791 year of age for metabolism pathways that have reached full maturity by this age; and (3) cases  
792 where the metabolite formation rate is considerably greater than the metabolite removal rate and  
793 the metabolite removal rate involves a cytochrome P450 (CYP) or other pathway that is  
794 immature early in life. Except for the third group, these conditions do not consider removal of  
795 the metabolite. As another example of identification of the rate-limiting step, if a chemical is  
796 cleared primarily by glucuronidation, the low activity at early ages suggests that particular  
797 attention should be paid to urinary metabolites to determine whether adequate clearance occurs  
798 via alternative conjugation pathway (e.g., sulfation).

799

#### 800 **4.2 Potential enhancements to the framework and data needs**

801

802 The framework presented here focuses on dosimetry comparisons between adults and children  
803 for inhaled gases and vapors. It could be further enhanced to consider variability, as part of  
804 evaluation of the appropriate intraspecies uncertainty factor. Only limited investigations were  
805 identified that evaluated variability within the child population. Pelekis et al. (2003) conducted  
806 PBPK modeling for methylene chloride using ranges for estimates of age-related physiological  
807 and biochemical parameters to develop annual average concentrations as population  
808 distributions. This approach could be used to evaluate total population variability.

809 Consideration of first principles would suggest that children would vary less than adults in many  
810 physiological parameters. While some physiological parameters (e.g., body fat) tend to exhibit  
811 greater variability at later ages, child variability in dose appears to be comparable to or greater  
812 than in adults. Renwick et al. (2000) reported that the magnitude of inter-individual variability

813 in drug clearance (expressed as a percentage) is not influenced by age. However, Hattis et al.  
814 (2003) found that the neonates had greater variability for some, but not all drugs and metabolic  
815 pathways. Common pathogenic processes, such as asthma, may also alter the respiratory tract  
816 dimensions, and thus the dosimetry, in ways not accounted for in the current analysis (Ginsberg  
817 et al. 2005).

818  
819 The framework focused on inhaled gases, and did not address inhaled particles or exposure via  
820 other routes. Extensive analyses of particle dosimetry have been conducted by Jarabek et al.  
821 (2005) and Ginsberg et al. (2005). Jarabek et al. (2005) used the Multiple Path Particle  
822 Dosimetry Model (MPPD)<sup>5</sup> to calculate the ratio of the human equivalent concentration (HEC)  
823 to laboratory animal exposure concentration for people ranging from 3 months to adulthood for  
824 poorly soluble nonfibrous particles (PSP) with mass median aerodynamic diameters (MMAD)  
825 ranging from 0.3 to 6  $\mu\text{m}$ . The authors used a dose metric of retained mass in the  
826 tracheobronchial region normalized to surface area, taking into account deposition and clearance  
827 (but not age-specific clearance). Ginsberg et al. (2005) used the ICRP (Smith 1994) model to  
828 model deposited dose per unit surface area for 3-month-old infants and adults as a function of  
829 particle size. Martonen et al. (2000) developed a particle deposition model that takes into  
830 account structural elements of the lungs and used the model to calculate deposited dose per unit  
831 surface area as a function of particle size for four age groups. These sorts of analyses, along with  
832 analyses built on more recent data, such as the deposition calculations of Oldham and Robinson  
833 (2006), based on asymmetrical growth geometries of the tracheobronchial region, can be used to  
834 develop a framework for exposure to particles and aerosols. Similarly, frameworks for the oral  
835 and dermal routes of exposure would be useful. For example, the oral route would need to  
836 consider the implications of first-pass metabolism. Interagency efforts (Jarabek 2000; Rigas et  
837 al. 2000) to develop dosimetric approach for the oral route (in addition to dermal dosimetry and  
838 improved inhalation dosimetry) are likely to provide additional guidance for this route.

839  
840 The intent of the proposed framework is to provide a structure for consideration of the  
841 implications of age-related kinetic differences for internal dose and to focus future research in  
842 this area. The results of the initial application of this framework suggests a selected number of

843 data gaps, where additional research may help to refine analyses of age-related differences in  
844 dosimetry. These areas include: (1) age-dependence of blood:air partition coefficients; (2) liver  
845 blood flow for children less than 4 years of age; (3) enhanced understanding of age-dependent  
846 changes in enzyme activities; and (4) characterization of extrahepatic metabolism.
